# Protecting Location Privacy with *K*-Confusing Paths Based on Dynamic Pseudonyms

KEN MANO<sup>1,a)</sup> KAZUHIRO MINAMI<sup>2,b)</sup> HIROSHI MARUYAMA<sup>2,c)</sup>

**Abstract:** As smart phones with a GPS receiver have been becoming popular recently, many people have realized the issue of protecting their location privacy. Previous research on location privacy mainly focuses on anonymization techniques for removing identifiable information from users' location traces. Although anonymized location data is useful to many applications, such as traffic monitoring, we can provide a new class of location-based services by utilizing path information of mobile users. In this paper, we present a dynamic pseudonym scheme for constructing alternate possible paths of mobile users to protect their location privacy. We introduce a formal definition of location privacy for pseudonym-based location data sets and show an efficient verification algorithm for determining whether each user in a given location data set has sufficient number of possible paths to disguise the user's true movements.

#### 1. Introduction

Nowadays a vast majority of people are using mobile devices equipped with a GPS receiver, and it thus becomes feasible to keep track of people's movements in a wide area by collecting GPS data from those mobile devices. Such a large volume of location data gives us a precise global view on people's mobility patterns, and we can thus support analytic location-based services, such as real-time traffic monitoring [5] and urban planning for future sustainable cities [14].

However, due to the significant concern for location privacy [1], the sharing of mobile users' location traces has been mostly restricted to anonymized data sets where users' identities are removed. We usually need to follow the practice of ensuring the k-anonymity [6], which degrades the granularity of location data to make sure that every location contains more than k people. Consequently, k anonymized data sets provide little information on users' mobility patters, which makes it difficult to link multiple data points produced by the same user.

There are, however, many situations where we can improve our analytic methods by considering users' mobility patterns. For example, Draffic [4] provides a statistical analysis of people's moving paths in sightseeing areas so that hotels and souvenir shops can take effective measures to draw more visitors and provide them with better services. Similarly, a shopping mall manager could allocate various stores in the mall such that customers' shopping experiences match their moving behaviors conveniently.

We, therefore, propose a new dynamic pseudonym scheme for constructing a location data set that retains users' path information while preserving their location privacy. Our basic approach is to exchange multiple users' pseudonyms only when they meet at the same location to eliminate the linkability of their pseudonyms before and after that exchange. Our privacy metrics requires that, at a given time *t*, every user has enough number of plausible paths heading towards *K* different locations.

To make this dynamic pseudonym-based scheme practical, we address an issue of multi-path inconsistencies among multiple users. Assuming that user's home locations are public knowledge available to an adversary, we find that all pseudonym exchanges cannot be effective; the adversary can detect global inconsistencies among multiple plausible paths taken by different users. It is thus not trivial to decide whether a given data set is safely publishable. We, therefore develop an efficient algorithm for determining whether it is possible to convert a given location data set into pseudonym-based data satisfying the (K, t)-privacy metrics.

The rest of the paper is organized as follows. We first introduce our system model for pseudonym-based location services in Section 2 and define our privacy metrics in Section 3. In Section 4, we describe a verification algorithm for a pseudonym-based location data set. We next discuss related work in Section 5 and finally conclude in Section 6.

# 2. System model

Figure 1 shows our system model for pseudonym-based location systems. We assume that a mobile user  $u_i$  carrying a GPS-enabled mobile devices periodically reports a triplet  $(u_i, l_k, t_k)$ , which indicates that user  $u_i$  is in location  $l_k$  at time  $t_k$ . The pseudonym-based location server receives from multiple users their identifiable location data, replaces their identities with pseudonyms, and provides location-based content providers,

c) hm2@ism.ac.jp

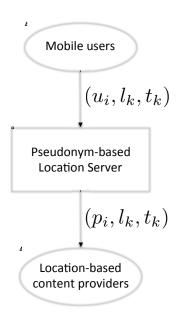

Fig. 1 System model. The pseudonym-based location server replaces a user's identity  $u_i$  with a pseudonym  $p_i$  before releasing location data to content providers.

such as traffic monitoring applications, with location data with pseudonyms.

We first introduce the following four sets U, P, L, and T to define our system model.

U: a set of m mobile users such that |U| = m.

P: a set of m pseudonyms such that |P| = m.

L: a set of symbolic locations.

T: a set of timestamps  $\{0, 1, \dots, t^*\}$  where  $t^*$  is the last timestamp.

We next define the following two functions.

**Definition 1 (Location function** *W*) The location function  $W: U \times T \to L$  returns a location *l* of user *u* at time *t*.

**Definition 2 (Pseudonym assignment function** N) The pseudonym assignment function  $N: U \times T \to P$  maps a user u at time t to a pseudonym p. We say that a user u owns a pseudonym p at time t if N(u,t) = p. For every time  $t \in T$ , the function  $N_t(u) \equiv N(u,t)$  is a one-to-one function from U to P.

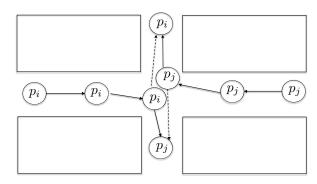

We now define a pseudonym-based data set parameterized by the functions W and N as the following set of triplets:

$$\{(p,l,t) \mid t \in T, u \in U, p = N(u,t), l = W(u,t)\}.$$

This data set represents the output from the pseudonym-based location server in Figure 1. In this paper, we consider a malicious content provider who legitimately obtains a data set from the pseudonym-based location server and tries to reveal the identity of a user corresponding to a certain pseudonym in the data set.

#### 3. Pseudonym-based location privacy

To replace the user identity on a given moving path with the static pseudonym does not necessarily protect the user's location privacy. We take an approach of changing each user's pseudonym dynamically to prevent inference attacks using external knowledge about her home location.

**Fig. 2** Example pseudonym exchange. Two users exchange their pseudonyms  $p_i$  and  $p_j$  at the intersection. The solid lines denote each user's actual path while the dotted lines denote an alternate possible path.

#### 3.1 Pseudonym exchanges

A user typically starts his moving path from her home and returns there again at the end. Therefore, if a user's home address is known to a malicious content provider, which is a well-agreed assumption in location privacy research [6], his moving path with the same pseudonym does not protect his location privacy; it is trivial to infer that the whole path belongs to the same user whose home address appears at both ends.

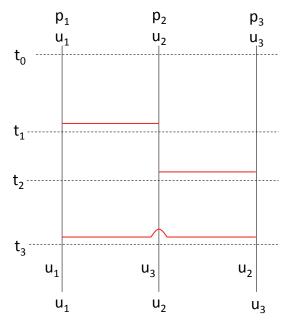

Therefore, it is necessary to change pseudonyms dynamically to prevent the above attack. The basic idea is to divide a whole path of the same user into multiple segments with different pseudonyms such that it makes infeasible to link any neighboring segments. However, when a user moves in an area where there is no other nearby users, it is straightforward to link two pseudonyms of the same user since we know that that user who is subjective to laws of physics cannot jump to a remote distant place in a short period.

To address this issue, we take an approach of exchanging multiple users' pseudonyms only when they meet at the same location (i.e., a mix zone [2]). Figure 2 shows an example of two users' exchanging their pseudonyms. Two users who own pseudonyms  $p_i$  and  $p_j$  respectively randomly exchange their pseudonyms when meeting at the intersection. Although the user who previously owns pseudonym  $p_i$  actually turns left at the corner, we consider the alternate path of turning right also possible. The other user similarly has the two possible paths after passing the intersection.

To consider only such valid pseudonym exchanges, we put the following constraint on the pseudonym assignment function N. For every pair of two different users  $u, u' \in U$  and time t > 0, if N(u, t - 1) = p and N(u', t) = p, then W(u, t - 1) = W(u', t - 1) holds. Intuitively, this constraint implies that if a user u' receives another user u's pseudonym p at time t, users u and u' must meet at the same location at the previous time t - 1.

#### 3.2 Multi-path consistency

If we consider the possible paths of a single user, whenever the user meets another user, we can add a new branch as a possible segment of the path. However, we assume in this paper that every user starts his path from his home location and then eventually returns there at the end of the path. Thus, we need to eliminate some possible branches if taking that direction makes it impossi-

**Fig. 3** An example of time-changing pseudonym assignments based on the ladder model.

ble for the user to return to his home location. Furthermore, even if one user  $u_i$  is able to return home with some possible path, another user  $u_j$  who exchange her pseudonym with  $u_i$  might lose her possible route to return home.

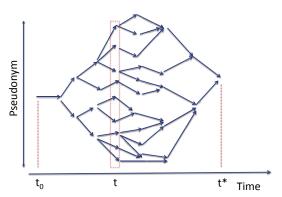

We elaborate this multi-path consistency issue with the ladder model in Figure 3. The ladder model represents a pseudonym assignment function N in a graphical way abstracting away each user's physical movements. Figure 3 shows an example ladder model for three users  $u_1$ ,  $u_2$  and  $u_3$ . The model denotes each pseudonym by a vertical line, and represent an encounter of multiple users by connecting those pseudonyms with a horizontal line. Assuming that time passes downward vertically, we specify the sequential order of users' meetings by the positions of horizontal lines.

Each pseudonym  $p_i$  is associated with a particular user at any give time t. Pseudonym  $p_1$ ,  $p_2$ , and  $p_3$  in Figure 3 are associated with users  $u_1$ ,  $u_2$ , and  $u_3$  respectively, both at the start and end times  $t_0$  and  $t_3$ . If we construct user  $u_1$ 's possible time-changing pseudonym assignments by exchanging pseudonyms, we obtain the following sequences:

- $(1)\ p_1 \rightarrow p_1 \rightarrow p_1 \rightarrow p_1$
- $(2)\ p_1 \to p_2 \to p_2 \to p_2$
- $(3) p_1 \rightarrow p_2 \rightarrow p_2 \rightarrow p_2$
- $(4) p_1 \rightarrow p_2 \rightarrow p_3 \rightarrow p_1$

If we consider the requirements that user  $u_1$  owns pseudonym  $p_1$  at times  $t_0$  and  $t_3$ , we must eliminate sequences (2) and (3) leaving (1) and (4) as possible sequences of pseudonym assignments. However, if we take the pseudonym sequence (4), users  $u_2$  and  $u_3$  are forced to take the pseudonym sequences  $p_2 \rightarrow p_1 \rightarrow p_1 \rightarrow p_3$  and  $p_3 \rightarrow p_3 \rightarrow p_2 \rightarrow p_2$  respectively, violating their endpoint requirements. Thus, it turns out to be impossible for user  $u_1$  to take the pseudonym sequence (4) above.

We should therefore consider possible pseudonym sequences of multiple users simultaneously to ensure that the resulting pseudonym assignment function N satisfy the following multi-

**Fig. 4** Concept of (K, t)-pseudonym location privacy. We assume that any pseudonym sequence following arrows from left to right can be produced by a certain multi-path consistent pseudonym assignment function N

path consistency requirement.

**Definition 3** (Multi-path consistent function N) We say that, a given location function W, a pseudonym assignment function N is multi-path consistent if

(1) 
$$\forall u, u' \in U, \forall t \in T > 0 : N(u, t - 1) = p \land N(u', t) = p \Rightarrow W(u, t - 1) = W(u', t - 1)$$
 and

(2) 
$$\forall u_i \in U : N(u_i, 0) = N(u_i, t^*) = p_i$$
.

#### 3.3 (K, t)-pseudonym location privacy

We argue that the number of possible pseudonym sequences is not appropriate privacy metrics for pseudonym-based location services. Consider the situation where two users move together taking the same moving path. If those two users possibly exchange their pseudonyms at each time, we end up having exponential number of possible pseudonym sequences! Therefore, we rather use the number of pseudonyms at a given time t on possible pseudonym sequences satisfying the multi-path consistency requirement as our location privacy metrics. Figure 4 shows such multiple pseudonym sequences of user  $u_i$ . There is only a single possible pseudonym at the initial time  $t_0$  and the last time  $t^*$ . On the other hand, user  $u_i$  can take multiple pseudonyms in the middle of those sequences. If user  $u_i$  can take more than or equal to K pseudonyms at a given time t, we say that user  $u_i$  satisfies (K, t)-pseudonym location privacy.

We now formally define the notion of (K, t)-pseudonym location privacy as follows.

**Definition 4** ((K,t)-**pseudonym location privacy**) Given a user  $u_i$ , we say that a location function W satisfies (K,t)-pseudonym location privacy if there exist more than or equal to K pseudonym assignment functions  $N_0, N_1, \ldots, N_K$  such that every  $N_l(u_i,t)$  for l=0 to K outputs a distinctive pseudonym.

### 4. Privacy evaluation algorithm

We present a privacy evaluation algorithm for computing how many possible pseudonyms each user  $u_i$  could have at a given time t. The algorithm takes two data structures A[t, i] and AM[t] as inputs. The matrix A[t, i] contains a set of users who can possibly take a pseudonym  $p_i$  at time t. Initially, for all i, each field A[t, i] contains the set of all users U except for A[0, i] and  $A[t^*, i]$ , which only contains a user  $u_i$ . Figure 5 shows an example of ma-

Time	p 1	p 2	p 3
t o	{ u 1}	{ u 2}	{ u 3}
t 1	{u <sub>1</sub> , u <sub>2</sub> , u <sub>3</sub> }	{u <sub>1</sub> , u <sub>2</sub> , u <sub>3</sub> }	{u <sub>1</sub> , u <sub>2</sub> , u <sub>3</sub> }
t 2	{u <sub>1</sub> , u <sub>2</sub> , u <sub>3</sub> }	{u <sub>1</sub> , u <sub>2</sub> , u <sub>3</sub> }	{u <sub>1</sub> , u <sub>2</sub> , u <sub>3</sub> }
t 3 (=t*)	{ u 1}	{ u 2}	{ u 3}

**Fig. 5** Example matrix A.

Time	Exchangeable pseudonyms	
t 1	{ p <sub>1</sub> , p <sub>2</sub> }	
t 2	{ p <sub>2</sub> , p <sub>3</sub> }	
t 3	{ p <sub>1</sub> , p <sub>3</sub> }	

**Fig. 6** Example list AM.

trix A. The list AM[t] contains a set of pseudonyms that can be exchanged by their owner users at time t. The example AM in Figure 6 shows that pseudonyms  $p_1$  and  $p_2$  can be exchanged by time  $t_1$ .

Taking A and AM as inputs, the algorithm keeps updating the content of A propagating the constraints at the both ends and outputs the final A, with which we can check how many pseudonyms a given user  $u_i$  takes at time t.

Algorithm 1 is the main program, which iteratively calls two functions O and I until matrix A cannot be updated any more. The function O sequentially narrows down the entries A[t,i] at time t by computing all the possible mappings from pseudonyms to users at time t using the mapping information at time t-1. The function I performs this task in the reverse order.

#### Algorithm 1 Main program.

```
1: while 1 do
2: prevA ← A
3: A ← O(A, AM)
4: A ← I(A, AM)
5: if A = prevA then
6: break;
7: end if
8: end while
9: return A
```

Algorithm 2 shows how the function O computes possible user-pseudonym mappings sequentially. The function O takes A and AM as inputs and updates A as follows.

# **Algorithm 2** Function *O* for computing possible user-pseudonym mappings sequentially.

```
1: seq \leftarrow \emptyset

2: \mathbf{for} \ t = 1 \rightarrow t^* \ \mathbf{do}

3: \mathbf{for} \ \mathbf{all} \ pseq \in compPrevSeqs(A, t-1) \ \mathbf{do}

4: seq \leftarrow seq \cup compCurrentSeqs(A, AM, t, pseq)

5: \mathbf{end} \ \mathbf{for}

6: A \leftarrow replaceRow(A, t, seq)

7: \mathbf{end} \ \mathbf{for}

8: \mathbf{return} \ A
```

The function *compPrevSeqs* in line 3 computes all the possible user-pseudonym mappings at time t-1 from A. We represent such a mapping as a sequence of users. For example, mapping  $(u_1, u_2, u_3)$  means that  $u_1, u_2$ , and  $u_3$  own pseudonyms  $p_1, p_2$ , and  $p_3$ , respectively. Line 3 stores such possible mapping in variable *psec* and computes all possible user-pseudonym

mappings by applying all possible pseudonyms exchanges specified in AM[t]. The variable seq in line 4 maintains all the user-pseudonym mappings at time t while iterating the for loop on each user-pseudonym mapping at time t-1. Finally, line 5 updates matrix A by replacing ith row with the new row computed from the user-pseudonym mappings in seq using the function replaceRow. The outermost while loop iterates this operation sequentially from time t=1 to  $t^*$ .

Similarly, Algorithm 3 shows how the function I computes possible user-pseudonym mappings in the reverse order. **Example:** Consider the matrix A in Figure 5 again. At time

**Algorithm 3** Function *I* for computing possible user-pseudonym mappings in the reverse order.

```
1: seq \leftarrow \emptyset

2: for \ t = t^* \rightarrow 1 \ do

3: for \ all \ nseq \in compNextSeqs(A, t) \ do

4: seq \leftarrow seq \cup compPrevSeqs(A, AM, t - 1, nseq)

5: end \ for

6: A \leftarrow replaceRow(A, t - 1, seq)

7: end \ for

8: return \ A
```

 $t_0$ , only mapping  $(u_1, u_2, u_3) \rightarrow (p_1, p_2, p_3)$  is possible. Therefore, the function compPrevSeqs in line 3 returns the sequence  $(u_1, u_2, u_3)$ , and that sequence is stored in variable psec. Next, the function compCurrentSeqs computes the possible mappings at time  $t_1$ . If we look up AM[1] in Figure 6, we learn that pseudonyms  $p_1$  and  $p_2$  are exchangeable at time  $t_1$ . Thus, we obtain two possible mappings  $(u_1, u_2, u_3)$  and  $(u_1, u_3, u_2)$ . This implies that  $A[1, 1] = \{u_1\}$ ,  $A[1, 2] = \{u_2, u_3\}$ , and  $A[1, 3] = \{u_2, u_3\}$ , and the function replaceRow takes care of this task.

There are a few possible extentions of the algorithm. First, an adversary might know that some location in the middle of a user's path is associated with a particular user. For example, the adversary might know some user's office location. We can handle such additional external knowledge of an adversary with a minor modification of the algorithm. We just need to define an initial matrix A where some elements in A corresponding to known intermediate locations contains a single user. Second, it is desirable to keep longer path segments in a data set as long as that set preserves given privacy metrics. We plan to extend the current algorithm such that it determines the minimum number of items in an array AM that are necessary to achieve given privacy metrics. Third, we would like to consider a realistic, weaker assumption that an adversary only obtains a partial data set, which does not users' all path information. We expect that there is a better strategy to disguise the users' actual paths while satisfying the privacy metrics.

#### 5. Related work

Several researchers [7], [9], [10], [12], [13] propose fine-grained access-control schemes based on rules for protecting location privacy in pervasive environments. Here, their focus is to provide a flexible policy language for protecting identifiable location data of mobile users. Hengartner [7] supports access-control policies considering the granularity of location information and time intervals. Myles [12] provides a XML-based autho-

rization language for defining privacy policies that protect users location information. Users must trust a set of validators that collect context information and make authorization decisions. Those schemes allows a user to define fine-grained access-control policies. Apu [10] provides users with an intuitive way of defining access control policies, which represent physical boundaries surrounding the users. However, no previous scheme considers the issue of inference based on the mobility patterns of users.

Location privacy has been studied heavily in the context of the anonymization and obfuscation of location data (See [11] for a comprehensive survey). The focus of research in this area is to ensure that no anonymized and/or obfuscated data is associated with an individual. For example, Gruteser [6] proposes a scheme that changes the granularity of location information to ensure that each location contains at least k users (i.e., k-anonymity).

Using pseudonyms is a promising way to make location data unlinkable to a particular user. Beresford and Stajano [2] first discuss the idea of dynamically changing pseudonyms in a mix zone where multiple people meet, in order to prevent an adversary from linking two pseudonyms of the same user. However, they only consider the situation where an adversary only has a local view of users' movements observing pseudonyms of entering or leaving the same mix zone. Hoh and Gruteser [8] present a path perturbation algorithm that adds noises to original location data so that each user can construct alternate possible paths by exchanging his pseudonym with those of other users when they meet at the same place. However, their scheme does not consider an adversary's external knowledge that can associates each user with a particular home location, as we assume in this paper. On the other hand, our scheme does not add noises to location data to increase the number of points where multiple users meet. Instead, our algorithm computes the number of all the combinations of users' valid alternate routes that satisfy the home locution constraints.

Buttyán et al. [3] study the effectiveness of changing pseudonyms in the context of vehicular networks. They evaluate the linkability of consecutive pseudonyms assuming an adversary who can monitor the location traces of vehicles at a limited number of places. We are more concerned with the indistinguishability of a user's *global* paths rather the unlinkability of pseudonyms in *local* areas. Also, their adversary model is different from ours; that is, the adversary in our model can obtain location data with pseudonyms at any places though the adversary cannot physically see the movements of users in any limited area.

#### 6. Conclusions

In this paper, we present a dynamic pseudonym scheme for constructing confusing paths of mobile users to protect their location privacy. We introduce a formal definition of location privacy based on pseudonyms and show an efficient verification algorithm for determining whether each user in a given location data set has sufficient number of possible paths to disguise the user's true movements. Future work includes providing a correctness proof of the algorithm and showing the effectiveness of our psuedonym-based scheme with actual data sets.
